the effect of various initial conditions. All of the chosen flares had full SMM instrument coverage with the exception of that on June 29, for which the main flare site was not observed with UVSP; in addition there are no Coronograph/Polarimeter (C/P) observations except for the June 29 event. Full details and bibliographies of published material on these flares appear in Appendix 5A; we summarize their properties in Table 5.1.1.

These all appear to be type B flares according to the classification scheme proposed originally by Tanaka (1983) and developed by Ohki et al. (1983) and Tsuneta (1983). None of the events we selected for detailed analysis is a type A or a type C flare. Type A flares are low-altitude, compact ($< 10$ arc sec) flares with very steep hard X-ray spectra and have been interpreted as purely thermal flares with temperatures of $3 \times 10^7$ to $5 \times 10^7$ K (Tsuneta et al., 1984a). Type C flares have virtually no impulsive phase, and the hard X-rays and microwaves appear to come, in at least one case, from altitudes of $5 \times 10^4$ km, near the top of a huge coronal loop (Tsuneta et al., 1984b). Cliver et al. (1984) have suggested that many flares that show similar characteristics to type C flares may be preceded some tens of minutes earlier by an apparently normal impulsive flare, presumably of type B. This classification scheme is described in more detail in Chapter 3 of this Workshop Report.

The concentration on type B flares was dictated by SMM observations, since the best observed flares were of this type. A further limitation of this work is the absence of a solar flare showing gamma-ray line emission. This again reflects the SMM data set in which there are no gamma-ray flares observed with the imaging instruments.

The growth of active-region magnetic energy has been estimated by using an MHD model given by Wu et al. (1983). This model is used to estimate the energy build-up during the pre-flare state on the basis of photospheric shearing motions. Wu et al. found that, in this model, the majority of the energy storage is magnetic; other forms (kinetic, potential, or thermal) are negligibly small in the pre-flare state. The physical basis of this MHD model is that observed sheared motion at the photosphere is the result of motion of the magnetic loop footpoints. This movement causes the magnetic field to twist and hence magnetic energy to be stored. Because the movement is so slow ($\sim 100$ m s$^{-1}$), the quasi-equilibrium state is always maintained so that the other energy modes do not increase as significantly as the magnetic energy.

5.1.8 Synopsis

In this investigation of flare energetics, observations characterizing the impulsive and gradual phases first were analyzed separately and then the results of the individual analyses were intercompared. Observational and analytic results related to the energetics of the impulsive phases of the events chosen for this study are presented in the following section. In Section 5.3, results obtained for the energetics of the gradual phases are presented. Investigation of the energetics relationships between the impulsive and gradual phases is described and their interpretation in terms of flare models is discussed in Section 5.4. In Section 5.5, an attempt is made to present a synthesis, based on the foregoing results, characterizing the total flare energy. Conclusions based on this work and observational requirements for addressing the remaining questions with instruments to be employed in the future are presented in Section 5.6. Appendix 5A describes the published results and observations of the five flares chosen for detailed study in this chapter. Appendix 5B contains a review of the observational characteristics of the impulsive phase of flares in general.

5.2 ENERGETICS OF THE IMPULSIVE PHASE

C. de Jager, M.E. Bruner, C.J. Crannell, B.R. Dennis, J.R. Lemen, and S.F. Martin

Provided by the NASA Astrophysics Data System
5.2.1 Introduction

In this section we concentrate on the impulsive phase, with particular emphasis on the energy content of the different components of the prime flares chosen for study (see Appendix 5A). From an energetics point of view, we are concerned primarily with high-energy electrons and protons and with plasma at temperatures above $10^4$ K. The different forms of energy include the kinetic energy of fast particles, and the thermal, convective, and turbulent energies of hot plasma. Our approach is in contrast to that used by Canfield et al. (1980), who presented estimates of the total radiant energy in different wavelength ranges. We have also measured the radiant energy in soft and hard X-rays, and in Hα for one flare, and the results are discussed in Section 5.4. We find that the energy radiated during the impulsive phase is negligible compared with the other components of the total flare energy. A more detailed discussion is given of the radiant energy as determined from the new Hα observations because they give a better estimate of the Hα radiant energy from one flare than that obtained previously (see Section 5.2.3.5).

To estimate the energies in the different flare components, it is necessary to make various assumptions about the physical conditions in the flares. Unfortunately, these cannot be determined unambiguously from the available observations. In particular, the thermal or nonthermal nature of the hard X-ray source is still unresolved, in spite of considerable evidence favoring the existence of beams of fast electrons. The spectrum of electrons below 20 keV, where most of the total energy may reside, is subject to large uncertainties. Also, only upper limits can be placed on the energy in protons above a few MeV from the gamma ray observations of the flares considered here. There is no information at all on the possible existence of protons at 10 keV to 1 MeV, which have been postulated to be an important component during the impulsive phase (Simnett 1984).

For the thermal plasma emitting soft X-rays, the filling factor and density distribution are also largely unknown. In addition, the available observations for the prime flares studied here do not provide information on the energy of plasma with temperatures below $10^4$ K.

As a result of these gaps in our knowledge, the energy of some potentially important components of flares cannot be estimated at all, and order-of-magnitude uncertainties exist in many of the estimates that can be made. Nevertheless, it is important in furthering our understanding of the flare processes to make these estimates as accurately as possible. Not only do they provide valuable limits on the total flare energy, but also, and possibly more importantly, they suggest how the energy is distributed among the components as a function of time during the various stages of the flare. The ability to determine these temporal variations in the distribution of the flare energy is improved markedly with the observations available for this study. Time resolutions as short as 0.1 s for the hard X-ray spectral observations and a few seconds for the X-ray imaging and soft X-ray spectral observations allow the flare energies to be determined on timescales an order of magnitude shorter than previously possible.

We begin Section 5.2.2 with a working definition of the impulsive phase and a brief review of the observations from which we obtained our energy estimates. We have concentrated on, but have not restricted ourselves to, the flares described in Appendix 5A that were selected by this team for detailed analysis. Estimates of the energies involved in energetic electrons, protons, and ions, chromospheric evaporation, and the thermal plasma at temperatures above $10^4$ K are given in Section 5.2.3. A more detailed description of the analysis done for the 1980 April 8 flare is given in Section 5.2.4. Finally, in Section 5.2.5 the main results are summarized and the relation between soft and hard X-ray sources is discussed.

5.2.2 The Characteristics of the Impulsive Phase

A review of the observational characteristics of the impulsive phase of flares is given in Appendix 5B, and a more extensive discussion is contained in Chapter 2 of this report. The most important characteristic of this phase is the impulsive release of energy on timescales of less than or about 10 s. This is evidenced by the plots of the intensity of the hard X-ray flux versus time that are shown in Figures 5A.2, 4, 7, 10, and 12. The hard X-ray spectral observations allow us to estimate the energy in fast electrons as discussed in Section 5.2.3.1. The soft X-ray flux shown as a function of time in the same figures rises continuously during the time that the hard X-rays are observed. Measurement of the line and continuum emissions allows us to estimate the energy of the hot plasma during this period (Sections 5.2.3.3 and 5.2.3.4).

5.2.3 The Determination of Component Energies

In this section we describe the methods that we used to determine the energies of several of the energetically most important flare components during the impulsive phase. We considered the following flare components: (a) impulsive energetic electrons that produce hard X-rays, (b) energetic protons and ions that produce gamma rays, and (c) thermal plasma that produces soft X-rays.

Two different estimates of the energy in the fast electrons were obtained from the hard X-ray observations; the first was obtained under the assumption that the X-rays were produced in non-thermal, thick-target interactions, and the second was obtained under the assumption that the hard X-rays and microwaves were produced in the same thermal source at a temperature in excess of $10^6$ K. The energy in
the soft X-ray-emitting plasma includes the kinetic energies of the convective and turbulent plasma motions in addition to the thermal energy. The radiative and conductive energy losses from this thermal plasma were also considered but were generally negligible during the impulsive phase, as was the gravitational potential energy of the upflowing plasma.

5.2.3.1 The Energy in Impulsive Energetic Electrons

It is almost universally accepted that solar flare hard X-rays are electron-ion bremsstrahlung. Since the bremsstrahlung cross-section as a function of energy is well known, it is possible to determine the instantaneous energy spectrum of the emitting electrons from the measured X-ray spectrum. Unfortunately, the interpretation of this result depends on the temperature and density of the plasma in which the electrons are interacting. Three basic models have been proposed for the production of the hard X-rays: models based on thick- and thin-target interactions and a thermal model (Brown 1971, Lin and Hudson 1976; Tucker 1975; Cranell et al., 1978). It is necessary to know, in any particular flare, which model (or combination of models) is correct, since the determination of the electron spectrum from the observed X-ray spectrum depends on the model assumed. More importantly, the correct model must be known to determine the role of the fast electrons in the overall flare energetics and ultimately to determine the fundamental energy release mechanism or mechanisms of the flare.

Recent observations have shown that the thick-target model is most likely to be the correct one, at least during the early part of the impulsive phase of some flares and for some fraction of the total hard X-ray flux. The arguments supporting this statement are presented in Appendix 5B. However, the subject is still controversial, and there is a strong possibility that a large fraction of the hard X-ray flux comes from a thermal source. This controversy is touched on in Appendix 5B, and a more detailed discussion can be found in Chapter 2 of this report.

From a spectral point of view, the hard X-ray observations used to make the energy estimates are consistent with either a thick-target or a thermal model. The X-ray spectrum can often be represented within the uncertainties of the data by either a power law or the exponential function expected for an isothermal source. Sometimes the thermal bremsstrahlung function fits the observations better on the rise and at the peak of impulsive bursts, whereas a power law fits better on the decline and in the valley between adjacent bursts (Cranell et al., 1978; Dennis, et al., 1981; Kiplinger et al., 1983a). However, a non-thermal source can produce an exponential spectrum, and a multi-temperature thermal source can generate a power-law spectrum (Brown 1974). In estimating the energy in fast electrons, therefore, we have chosen to make the calculations both for a thick-target model by assuming a power-law spectrum and for a single-temperature thermal model. The true model is probably some hybrid of the two, but we are unable to determine the proportions of the thermal and non-thermal components from the available observations.

(i) Non-thermal Model. The X-ray spectra of the impulsive bursts have been determined from HXIS and HXRBs observations by using techniques described by Batchelor (1984). By assuming thick-target interactions, we can determine the energy and the number of energetic electrons involved in the bombardment of the lower corona and the chromosphere from these X-ray spectra.

For calculating the energy in fast electrons, one usually assumes that the incident X-ray spectrum is a power-law of the form

\[ I_\gamma(e) = \alpha e^{-\gamma} \text{ photons cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}, \]  

(5.2.1)

where \( I_\gamma(e) \) is the differential flux of photons with energy \( e \) in keV, and \( \alpha \) and \( \gamma \) are parameters determined from least-squares fits to the spectral data. The standard thick-target-model equations are used to relate the measured X-ray spectrum to the spectrum of the electrons producing the X-rays (Brown 1971; Hoyng et al., 1976; Lin and Hudson 1976). The electron spectrum that results in a power-law X-ray spectrum is also a power law, of the form

\[ I_e(E) = \beta E^{-\delta} \text{ electrons s}^{-1} \text{ keV}^{-1}, \]  

(5.2.2)

where \( I_e(E) \) is the differential flux of electrons with energy \( E \) that enter the thick target. The parameters \( \beta \) and \( \delta \) are related to \( \alpha \) and \( \gamma \) by the following equations:

\[ \beta = 3 \times 10^{33} \alpha \gamma (\gamma - 1)^2 \]  

(5.2.3)

\[ b(\gamma - 1/2, 1/2), \]

\[ \delta = \gamma + 1, \]  

(5.2.4)

where \( b(\gamma - 1/2, 1/2) \) is the beta function.

The total energy in electrons that enter a thick target during a flare is obtained from the equation

\[ W(>E_0) = \int E^{-\delta+1} dE = \int E^{-\delta+2} (\delta - 2)^{-1} dE \]  

(5.2.5)

In this expression, the lower energy cut-off, \( E_0 \), must be imposed on the electron spectrum to ensure that \( W \) remains finite, but it is very difficult to determine the correct value of \( E_0 \) from the observations. This difficulty introduces the largest uncertainty in the estimate of \( W \). A cut-off in the electron spectrum at \( E_0 \) would appear as a flattening of the X-ray spectrum at X-ray energies below \( E_0 \). The X-ray spectrum cannot get significantly flatter than \( e^{-2} \), however, as
a result of the Bethe-Heitler formula for the bremsstrahlung cross section, regardless of the shape of the electron spectrum. Such a flattening at low energies is sometimes observed in the X-ray spectrum at the time of impulsive peaks in the flux, although it can be masked by the soft X-ray flux from the $\sim 20 \times 10^8$ K plasma. As a suitable approximation, $E_0 = 25$ keV has been taken for the calculation of the values of $W$ given in Tables 5.2.1 and 5.2.2.

(ii) Thermal Model. An alternative model for the production of the hard X-rays is one in which the source is thermal and the electron spectrum can be represented with a single effective temperature. The X-ray continuum spectrum is then of the form expected from an electron population with a Maxwellian velocity distribution, i.e.,

$$I_x(\epsilon) = 1.08 \times 10^{-42} \ Y \ \epsilon^{-1} \ T^{-0.5} \ G(\epsilon, T) \ \exp(-\epsilon/kT)$$
photon/cm$^2$ s$^{-1}$ keV$^{-1}$, \hspace{1cm} (5.2.6)

where Y is the thermal emission measure (in cm$^{-3}$), T is the effective temperature of the source (in degrees K), G(\epsilon, T) is the "total effective Gaunt factor" as a function of \epsilon and T as given by Meive and Gronenschild (1981) and Matteson (1971), and k is the Boltzmann constant. The parameters Y and T are selected to give a least-squares fit to the HXRB spectral data (Batchelor 1984).

The thermal energy in the isothermal plasma emitting the hard X-rays is given by the relation

$$E_{\text{th}} = 4.14 \times 10^{-16} \ Y \ T/n \ \text{ergs} \hspace{1cm} (5.2.7)$$

where n is the electron density (in cm$^{-3}$). Since Y = $n^2 \ V_p$, where $V_p$ is the volume of the plasma (in cm$^3$), the thermal energy can be rewritten as

$$E_{\text{th}} = 4.14 \times 10^{-16} \ Y^{1/2} \ V_p^{1/2} \ T \ \text{ergs}. \hspace{1cm} (5.2.8)$$

Thus, either the density or the volume of the source must be known before $E_{\text{th}}$ can be determined.

An estimate of the source volume can be obtained from the microwave data with the additional assumptions that the observed optically-thick microwave emission originates with the hard X-rays in a common, thermal source. In such a model, the frequency-dependent flux $I_{\mu}(f)$ in the optically-thick portion of the microwave spectrum is related to the projected source area $A_{\mu}$ (in cm$^2$) by the expression

$$I_{\mu}(f) = 1.38 \times 10^{-26} \ f^2 \ A_{\mu} \ \text{ergs} \hspace{1cm} (5.2.9)$$

where $I_{\mu}(f)$ is measured in solar flux units (1 sfu = $10^{-22}$ W m$^{-2}$ Hz$^{-1}$) and f is the observing frequency in GHz (Crannell et al., 1978). This relation provides a means for determining the area of the source region through the use of the temperature determined from the hard X-ray observations and the microwave flux measured at fixed frequencies in the optically thick portion of the spectrum.

The volume of the source ($V_p$) can be estimated from $A_{\mu}$ by

$$V_p = A_{\mu}^{3/2}. \hspace{1cm} (5.2.10)$$

so that the expression for the thermal energy can be rewritten as

$$E_{\text{th}} = 4.14 \times 10^{-16} \ Y^{1/2} \ A_{\mu}^{3/4} \ T \ \text{ergs}. \hspace{1cm} (5.2.11)$$

Similarly, the magnetic field associated with the source region can be inferred from the calculated temperature and the turnover frequency in the microwave spectrum, $f_t$ (in GHz), according to the following simplified relation (Karpfen, et al., 1979):

$$B = 1.86 \times 10^4 \ [f_t/(1.66 \times 10^8 + T)]^{14}. \hspace{1cm} (5.2.12)$$

The values of the calculated parameters are given in Table 5.2.3.

5.2.3.2 Estimates of the Energy Content of the Energetic Protons and Ions

The three prime flares listed in Table 5.2.4 were observed with GRS at energies above 300 keV. However, none of them produced detectable nuclear line emission above the GRS sensitivity threshold. Therefore, although we have no direct measure of the gamma-ray flux resulting from the interactions of energetic protons and ions, we do have upper limits on this flux for each of the events which produced continuum emission above 300 keV. These upper limits can be used with the model described by Ramaty (1982) to deduce upper limits on the energy content of the energetic protons and ions above a few MeV. The values obtained in this fashion for each of the three flares are presented in Table 5.2.4.

In addition to these upper limits, an estimate of the energy content of the energetic protons and ions can be obtained from the observed continuum emission above 300 keV and an empirically determined scaling factor relating the continuum flux and the nuclear line emission. The values presented in the fourth and fifth columns of Table 5.2.4 are energy estimates obtained with this scaling procedure used in conjunction with the model described by Ramaty (1982), and the same spectral shape as was the upper limits. For two of the three flares, the estimates are significantly less than the corresponding upper limits. For one flare, the estimates are greater than the upper limits, but the difference is not significant.

Realistic uncertainties in the values of the estimates and upper limits are dominated by the uncertainty in the choice of the appropriate spectral form. In Ramaty's model calculations, a Bessel function spectral form is used. Alternative

The values listed under the column heading "\(>10 \text{ MeV}\)" are upper limits on the total energy content of protons and ions with kinetic energies greater than 10 MeV. The values listed under the column heading "\(>0 \text{ MeV}\)" are upper limits on the total energy content of all protons and ions included in the energetic particle spectrum. Each event is designated by its date, start time, and \(\Delta t\), which specifies the duration of the impulsive phase over which the flux values were integrated.

The radiation sources, such as a power law with the low-energy cut-off as a free parameter, could change all of these values by several orders of magnitude, as the bulk of the energy is probably in protons and ions with energies \(<1 \text{ MeV}\).

5.2.3.3 Thermal Energy of the Soft X-ray Emitting Plasma

As discussed in Appendix 5B, there is considerable observational evidence that the thermal plasma emitting soft X-rays, i.e., plasma with T greater than or about \(3 \times 10^7\)K, is not isothermal, especially during the impulsive phase. Nevertheless, we have made estimates of the total thermal energy by assuming a single-temperature thermal source for this radiation. These estimates clearly are subject to large, systematic errors, but they should give reasonable results over restricted temperature ranges. In particular, they are expected to be more reliable at the end of the impulsive phase, when the thermal energy reaches its maximum value. At that time the plasma is closer to thermal equilibrium, and a single-temperature analysis should be more appropriate. Tables 5.2.1 and 5.2.2 show estimates of these peak thermal energies for direct comparison with the total energy in fast electrons entering a thick target during the impulsive phase.

A more comprehensive analysis technique that involves estimating the differential emission measure as a function of temperature was also used for the cases in which sufficient data were available (see Section 5.3.2). The results

Provided by the NASA Astrophysics Data System
should give more accurate energy estimates, but again, because of the available observations and the uncertainty in the FCS calibration, they apply only in the restricted temperature range above 10⁷K.

For the single temperature analysis a technique was used that is similar to the one described in Section 5.2.3.1(ii) for the thermal analysis of the hard X-ray spectrum. The single temperature analysis was carried out using the six HXIS energy bands to derive a temperature and emission measure. The same equations used for the hard X-ray analysis were also used here with the addition of estimates of the line fluxes which contribute to the counting rate in the lower energy bands.

The estimates of the source volume, required to determine the thermal energy, were obtained from the HXIS fine-field-of-view images in bands 1, 2, and 3 (3.5 to 11 keV) after the smearing effects of the instrument collimators were removed. A simple iterative technique based on the method given by Svetska et al. (1983) was used to deconvolve the collimator response. Unlike Svetska et al., however, we continued the iterations until the χ² statistic stopped decreasing rather than when χ² became less than the number of degrees of freedom. In this way the most likely value of the source area was obtained. For the smaller sources, this was as much as a factor of 5 smaller than that which would have been obtained by the original method given by Svetska et al. Further details about the procedure are given by Dennis et al. (1984a).

In contrast to the microwave source area Aₘ discussed in Section 5.2.3.1(ii), this measured source area is directly determined, but it is only the apparent area. The true area may be much smaller and may contain fine structure that was unresolved with the HXIS 8 arcsec FWHM spatial resolution. Again, we must assume some reasonable geometry to determine the source volume Vₘ from this measured area Aₘ. For most simple geometries

\[ Vₘ = 0.5 \ Aₘ^{3/2}. \]  
(5.2.13)

We include the filling factor φ such that

\[ Vₚ = φ \ Vₘ \]  
(5.2.14)

to allow for the possibility that the source was unresolved. Thus, we obtain the following relation for the energy in the plasma, assuming it to be isothermal:

\[ Eₘ(<10^8 \ K) = 4.14 \times 10^{-16} \ \text{(Y} \ φ \ Vₘ\text{)}^{1/2} \ \text{T ergs.} \]  
(5.2.15)

(c.f. Equation 5.2.8).

In many cases, the source at the time of the peak in soft X-rays was made up of at least two separate components: a small, compact source referred to as the "kernel" by de Jager et al. (1983) and a more extended source with lower counting rates per pixel, referred to as the "tongue". In the present analysis, it was possible to estimate the areas of these two sources separately. Further, by assuming that their temperatures were the same, it was possible to determine their relative contribution to the total emission measure. Thus, the thermal energy in each component could be determined separately (Dennis et al., 1984a). The different parameters computed for the kernel and the tongue for those flares in which they could be distinguished are listed in Tables 5.2.1 and 5.2.2.

### 5.2.3.4 Convective and Turbulent Motions

The BCS spectra in the Ca XIX and Fe XXV channels show a blue-shifted component and line broadening during the impulsive phase of many events. These have been interpreted as resulting from upward motions and turbulent motions, respectively (Antonucci et al., 1982). The energies associated with these bulk plasma motions can be significant and have been estimated, when possible, for the prime flares studied by this group.

The most extensive analysis of bulk motions has been carried out by Antonucci et al. (1982, 1984). In this analysis of 25 disk flares, the observed Ca XIX spectra were fitted with a synthesized spectrum consisting of the spectrum expected from a stationary, isothermal but turbulent source plus the spectrum from an upwardly moving source with the same electron and Doppler temperatures as the stationary source. In this way, the electron and Doppler temperatures and the emission measure of the source of the principal spectrum were derived together with the flow velocity and the emission measure of the moving source.

To compute the convective and turbulent energies from these parameters, it is necessary to know the mass of the plasma involved. Antonucci et al. (1984) were able to derive values for the mass of the upflowing plasma by requiring that the evaporating material supply sufficient mass and energy to account for the observed coronal plasma during the thermal phase of the flare. The volume of this plasma can be inferred from the HXIS images, as already discussed in Section 5.2.2. Furthermore, an estimate of the cross-sectional area and separation of the loop footpoints where the chromospheric evaporation is most likely to take place can be obtained from the high energy HXIS images in energy bands 5 and 6 between 16 and 30 keV.

From the values given by Antonucci et al. (1984), we have computed the convective (E_{con}) and turbulent (Eₜ) energies for three of the prime flares. These energy values are given in Table 5.2.5, with the values given by the same authors for the increase (E_{SXR}) in the total energy of the coronal plasma plus the radiative and conductive losses (E_{loss}) during the evaporation process, i.e., E_{SXR} = Eₘ + Eₜ + E_{loss}.

The two remaining prime flares not analysed by Antonucci et al. (1984), i.e., 1980 August 31 and June 29, showed very little blue shift or asymmetric line broadening. The 1980 June 29 flare occurred on the limb, and such flares typically do not have blue-shifted components or asymmetrically broadened X-ray line profiles during the impulsive phase. Presumably this is because the line of sight of the instrument is perpendicular to the direction of motion of the bulk of the moving plasma. However, symmetrical line broadening in excess of what would be expected from purely thermal motions is observed for limb flares, especially during the impulsive phase. The 1980 August 31 double flare was a compact event, which showed very little asymmetric broadening during either flare (Strong et al., 1984).

The procedure to determine the turbulent energy from the symmetrical line broadening was similar to that described above. Spectral fits were obtained over the full wavelength range in the BCS Ca XVII-XIX and Fe XXIV-XXV channels. A synthetic spectrum was computed by assuming an isothermal model, and a best fit to the data was obtained which minimized the \( \chi^2 \) parameter by varying the electron temperature, total line width, and emission measure. The excess line broadening was determined by subtracting the instrumental width and the contribution due to thermal motions (assuming that the ion and electron temperatures were equal). For the 1980 June 29 flare, the effect of the X-ray source size in the East-West direction (0.75 arc min) was included. The excess line broadening can be expressed as an ionic velocity. The values of this parameter obtained from the calcium and iron observations were found to be in good agreement with one another, giving confidence in the instrumental calibrations and justifying for the isothermal assumption used in determining the excess line width.

The resultant turbulent energies are shown in Figure 5.3.8 and 5.3.9 for the two flares under consideration. The mass of the plasma was determined from a multi-thermal analysis for the emission measure, assuming that the volume remained constant throughout the flare. A filling factor of unity was used, and the volumes were assumed to remain constant equal to the values derived from the HXIS images given in Table 5.2.3. Since the mass was determined from a multi-thermal emission measure model for temperatures above 10^5 K, the calculated turbulent energies are appropriate for the high temperature component only. The results are summarized in Table 5.2.6. The turbulent energies are a factor of 20 to 100 less than the energies in fast electrons above 25 keV computed assuming thick-target interactions.

5.2.3.5 Radiant Energy in H\( \alpha \)

An estimate of the radiant energy in H\( \alpha \) during the impulsive phase of the second flare on 1980 November 5 was made on the basis of spectra taken with the multi-slit spectrograph operated at the San Fernando Observatory. No useful spectra were obtained until the instrument was triggered into the flare mode at 22:34:21 UT, the beginning of the second hard X-ray maximum of the second flare (see Figure 5A.12). After that time one spectrum was recorded on 35 mm film every 2 s with the slits stepping 2.6 arcsec between exposures. The extremities of the flare kernels at the flare maximum were approximately 31 arc sec apart in the direction of slit motion. Consequently, with the 51 arc sec slit spacing, the flare kernels were sampled in groups of 12 consecutive spectra with intervening intervals of 20 arc sec when the slits were not positioned on any bright part of the flare. The total radiant H\( \alpha \) intensity, \( \Delta I \), in excess of the quiet Sun was obtained from the photographically recorded spectra by using the relative continuum intensity given in the Photometric Atlas of the Solar Spectrum (Minnert et al., 1940) and the Labs and Neckel (1968, 1970) absolute calibrations. The three series of spectra obtained before the end of the impulsive phase gave nearly the same value for \( \Delta I \): 1.5 \times 10^4 ergs s\(^{-1}\) sr\(^{-1}\).

The total energy radiated in H\( \alpha \) can be determined from the measured intensities and the area \( A \) of the flare kernel of < 100 (arc sec)\(^2\), determined from the HeI D\(_3\) filtergrams (see Appendix 5A). The average power \( P \) radiated in H\( \alpha \)
during the second peak of the flare was computed from the relation (Canfield et al., 1980):

\[ P = 2\pi\Delta I \Delta = 4.9 \times 10^{26} \text{ ergs s}^{-1}. \]

Since the second peak lasted for \( \sim 120 \) s and contained only about a quarter of the total number of hard X-rays detected with HXRBs during the flare, our best estimate for the total He \(_2\) radiated energy during the impulsive phase of the flare is \( 4(P \times 120 \text{ s}) = 2.3 \times 10^{29} \text{ ergs} \).

### 5.2.4 The 1980 April 8 Flare

The April 8 flare is unique among the set studied by us in that it was observed with the P78-1 satellite as well as with SMM. We have therefore chosen this event to illustrate the various approaches that we pursued in our investigation of flare energetics. Observations of hard X-ray spectra were obtained with HXRBs, images and X-ray spectra were obtained with HXIS, soft X-ray spectra were obtained with BCS, and images in the principal FCS set of lines were obtained throughout this event. UVSP observations produced a series of images in the density-sensitive lines of Si IV and O IV before the onset of the impulsive phase. The P78-1 observations include soft X-ray spectra, from which we selected the O VII, Ca XIX, and Fe XXV lines for analysis.

In Figure 5.2.1 we show the radiated energy in hard X-rays as a function of time for this flare as determined from power-law fits to the HXRBs spectral data. The power-law spectral index \( \gamma \) is plotted as a function of time in Figure 5.2.2, together with the power flux of electrons above 30 keV entering a thick target as derived from the power-law fits. Figure 5.2.3 shows the energy in electrons above 25 keV integrated from the start of the flare for comparison with the thermal energy in the soft X-ray emitting plasma. Two estimates of the thermal energy are plotted. The one marked "HXIS (single temp)" was obtained from isothermal fits to the HXIS data as described in Section 5.2.3.3. The source density was assumed to be \( 10^{10} \text{ cm}^{-3} \) to obtain the plotted energy from the temperature and emission measure resulting from the fitting procedure. The points marked "BCS and HXIS" were obtained from a full differential emission measure (DEM) analysis with both BCS and HXIS data. The DEM distribution was integrated over temperatures from \( 10^7 \) to \( 5 \times 10^7 \text{K} \), and the source volumes obtained from HXIS images were used to compute the total thermal energies plotted.

The effect of different assumptions about the temperature distribution and the densities or volumes can be seen by comparison of the two curves shown in Figure 5.2.3 for the thermal energy. If we force the single-temperature model to agree with the multi-thermal analysis at the end of the impulsive phase, say at 03:08 UT, by adjusting the assumed density, then the multi-thermal analysis gives about an order of magnitude more energy near the start of the impulsive phase, say at 03:04 UT. This is presumably because of a lower-temperature component with \( T \) near \( 10^7 \text{K} \) that does not give a significant contribution in the HXIS energy range, at least not so that the single temperature analysis can reveal its presence. This result suggests significant preheating before the appearance of hard X-rays for this particular flare.

Figure 5.2.4 shows the results of the analysis of the hard X-ray data, assuming that the source was thermal and that the electron spectrum could be represented with a single effective temperature. The effective temperature and emission measure are plotted as a function of time, as obtained from least-squares fits to the HXRBs data. The total energy of the plasma is also plotted as a function of time, assuming a source density of \( 10^9 \text{ cm}^{-3} \).

The density determinations made possible with observations of the helium-like lines of O VII, obtained with the P78-1 satellite, enable us to obtain an estimate of the density and hence the volume of the soft X-ray emitting source at \(-2 \times 10^9 \text{K} \) (Doschek et al., 1981), and these are plotted as a function of time in Figures 5.2.5 and 5.2.6. During the impulsive phase of the flare, the density and hence the volume derived from the P78-1 observations are uncertain by as much as an order of magnitude, but after the peak in the density.
1980 APRIL 8

Figure 5.2.2 Power flux of electrons above 30 keV into a thick target computed from the HXRBS data for the 1980 April 8 flare. The top plot shows the HXRBS power-law spectral index on the same time scale.

The parameters characterizing the chromospheric evaporation for the 1980 April 8 flare are plotted versus time in Figure 5.2.7. The plotted parameters were determined from spectral fits to Ca XIX spectra determined with BCS as described in Section 5.2.3.4. The corresponding total energies are given in Table 5.2.5.

5.2.5 Discussion

We have computed the impulsive phase energies in various components of the prime flares selected by this group and the main results are summarized in Table 5.2.7.

The total energy in fast electrons during the impulsive phase and the thermal energy in the soft X-ray emitting plasma at the end of the impulsive phase are the two most important components of these flares from an energetics standpoint. If the hard X-rays are produced by thick-target interactions of the fast electrons, the total energy in electrons above 25 keV is almost embarrassingly large compared with the energy of the soft-X-ray-emitting plasma. If the lower-energy cut-off is dropped to 10 keV, as appears reasonable, at least for the early part of the impulsive phase of some flares, then the calculated energy in fast electrons becomes even higher. A plot of the thermal energy of the soft-X-ray-emitting plasma against the energy in electrons above 25 keV, $W(>25\text{ keV})$, is shown in Figure 5.2.8. A strong correlation with a coefficient of 0.8 is found between these two quantities. Although this correlation is considerably better than that expected from the Big Flare Syndrome (Kahler 1982), correlations calculated for different models show similarly high correlation coefficients (see Section 5.4.2). There are other serious problems with this correlation, so that it cannot be used to argue in favor of thick-target interactions or of a causal relation between the fast electrons and the thermal plasma. These problems are discussed briefly here.

1. The low-energy cut-off in the electron spectrum is unknown and may be different for different flares. This can cause order-of-magnitude errors in the estimates of the total energy in fast electrons.

2. The filling factor for the thermal plasma is unknown and may be different for different flares. Introduction of a fractional filling factor will decrease the thermal energy by $\phi^{1/2}$. It has been argued that $\phi$ was as small as $10^{-2}$ during the flare on 1980 April 30 (de Jager et al., 1983), $3 \times 10^{-3}$ to $3 \times 10^{-2}$ during the flare on 1980 November 5 (Wolfson et al., 1983), and $10^{-4}$ for the same flare (Martens et al., 1984). Filling factors this small would decrease the thermal energy by one or two orders of magnitude, thus destroying the similarity with the energy in fast electrons.

3. The hard X-ray spectral fits may be contaminated by the high-energy tail of the thermal distribution, particu-
Figure 5.2.3 Energy in > 25 keV electrons and in the soft-X-ray-emitting thermal plasma as a function of time for the impulsive phase of the 1980 April 8 flare. The energy in electrons above 25 keV was computed from power-law fits to the HXRBS data assuming thick-target interactions. The energy in the soft-X-ray-emitting plasma was computed in two ways. In one case marked “HXIS (single temp)”, a single temperature thermal spectrum was fitted to the HXIS spectral data by using the results of the HXIS count rate prediction program. In the other case, a full multi-temperature DEM analysis was carried out using BCS and HXIS data for temperatures from 10^7 to 5 × 10^7 K.

(4) Not all of the hard X-rays may have been produced in thick-target electron interactions. A considerable fraction of the total X-ray flux may be produced from a thermal source, particularly in the later stages of the impulsive phase when footpoints can no longer be resolved in the hard X-ray images. If the X-rays are mainly from a thermal distribution of electrons, then a value of ~2 × 10^{16} cm^{-3} for the unknown density will make the energy in such a thermal source equal to the energy calculated assuming thick-target interactions (Smith and Lilliquist, 1979). With the thermal model described in Section 5.2.3.1 (ii) in which the hard X-rays and microwaves are assumed to come from a common source, the density and energy content of the energetic electrons are uniquely specified by the observed emissions. The total energy integrated over the whole flare, however, depends on the rate of energy input to the electrons and on unspecified loss mechanisms. It is, therefore, not known if the energetic electrons could supply the thermal energy of the plasma at temperatures greater than or about 10^7 K. Smith (1985) suggests that only 10% or less of the hard X-rays are produced in thick-target interactions, mostly in the first 1 or 2 min of the impulsive phase. He postulates that the energy release mechanism puts most of the energy into heating after that time. Rust (1984) also argues that only a small fraction of the observed chromospheric evaporation is produced by electron beams and that such

beams are energetically unimportant when compared to conduction.

In addition to the total energies of the impulsive phase, we have determined the energies as a function of time for some flares. Figure 5.2.3 is a plot of the different components of the flare energy as a function of time for the impulsive phase of the 1980 April 8 flare; Figure 5.2.9 is a similar plot for the 1980 May 21 flare, from Antonucci et al. (1984). In both cases, the build-up in thermal energy of the soft X-ray emitting plasma is consistent with the deposition of energy into a thick target by fast electrons.

For the May 21 flare, when the impulsive phase was relatively long, lasting for about 10 min until ~21:05 UT, the radiation losses are significant. Depending on the assumed volume, the thermal energy is between 1 and 6 times larger than the accumulated radiation losses at 21:05 UT. For the other flares with shorter impulsive phases, the radiative losses tend to be less important, as can be seen from a comparison of $E_{\text{rad}}>10^7$K and $E_{\text{SXR}}$ in Table 5.2.7.

5.2.6 Conclusion

It is clear that with the present state of the observations, the study of flare energetics during the impulsive phase is a very poor way of discriminating between different flare models. Ideally, it would be possible to determine the fraction of the total energy that goes into accelerating electrons versus the fraction directly heating the plasma. We are clearly a long way from being able to make that differentiation,
Figure 5.2.7 The time variation of the parameters characterizing the chromospheric evaporation for the 1980 April 8 flare. The following derived quantities are plotted as a function of time with the Ca XIX and hard X-ray rates shown for reference: the temperature difference $\Delta T$ between the ion and the electron temperatures, the upward component of the velocity $v'$, the electron temperature $T_e$, and the Ca XIX emission measure $Y$ (from Antonucci et al., 1984.). Note that the plotted difference, $\Delta T$, between the Doppler and electron temperature is a measure of the non-thermal line broadening attributed to plasma turbulence.

Although the data, particularly the hard X-ray imaging observations, suggest that some significant fraction of the energy does go to accelerate electrons to energies above 20 keV.

To improve this situation, future observations must address the fundamental constraints which have limited our analysis. The most important of these is the resolution of the thermal or non-thermal character of the hard X-ray source. It is not clear at present how this will be achieved, although hard X-ray imaging to higher energies and with better spatial and temporal resolution will be important. Also, measurements of the hard X-ray spectrum with higher spectral resolution than is possible with scintillation counters will allow spectra steeper than $\epsilon^{-7}$ to be determined and will also enable X-rays from plasma with temperatures up to $3 \times 10^7$K to be separated more clearly from the higher-energy component. Moreover, by combining observations with improved spectral and spatial resolution, the spectrum of accelerated electrons below 20-30 keV can be determined, so that a better estimate of the total energy in these electrons can be made.

As far as improvements in the estimates of the energy in the soft-X-ray emitting plasma is concerned, it is clear that better estimates of the emission from plasma at temperatures below $10^7$K must be made and that the filling factor must be determined at all energies. A wide range of temper-

atures is involved during the impulsive phase, and single
temperature analysis is inadequate, given the improvements in
the observations. Multi-thermal analysis techniques,
however, are limited in the detail with which the tempera
ture distribution can be determined, even with more accurate
observations.

5.3 THE ENERGETICS OF THE
GRADUAL PHASE

5.3.1 Introduction

The gradual phase of a flare is best characterized by the
smooth rise and decay of the soft X-rays (see Figure 5A.2).
Just from inspection of the soft X-ray light curves of some
typical flares, it is evident that the gradual phase comprises
several different stages. During the rise of the X-ray emis-
sion, a completely different energy budget from that of the
decay will be produced. Many flares show multiple peaks
in their light curves, indicating that energy is released after
the initial burst. The location of any such secondary energy
release will also profoundly affect the relative importance
of the terms in the energy budget of the flare.

The soft X-ray emission produced by the higher-
temperature (> 10^7 K) plasma rises and decays more rapidly
and peaks earlier than that produced by the cooler plasma
(10^6 – 10^7 K). The impulsive phase usually occurs during
the rise of the soft X-ray emission but there is no clear
evidence of an impulsive component in the soft X-ray signal.

Hence, in an energetics study the important question arises
of what, if any, is the link between the impulsive and grad-
ual phases.

We have avoided using the term "thermal phase" be-
cause it is misleading; a number of non-thermal energetics
terms are associated with the gradual phase. The mass
motions are an example; it is not clear whether they are peculiar
to the early stages of a flare or whether they are also present
later in the flare, which seems to be likely, as mass motions
have been detected even in quiescent active regions (Acton
et al., 1981). We therefore attempted to evaluate the non-
thermal terms as well as the thermal energy throughout the
gradual phase of the five prime flares.

As the flare observations made with SMM were not spe-
cifically designed to address the energetics problem, our
choice of flares (see Appendix 5A) represents a compromise.
We identified a number of different "types" of flares that,
although sharing the same physical processes, had somewhat
different physical characteristics.

The Skylab Solar Flares Workshop (Sturrock 1980a) laid
the foundations for the methodology used in this section, and
we compare our results with those in the chapter by Moore
et al. (1980), who reached five main conclusions about the
gradual phase:

- the typical density of the soft X-ray emitting plasma
  is between 10^{11} and 10^{12} cm^{-3} for compact flares and
  between 10^{10} and 10^{11} cm^{-3} for a large-area flare;
- cooling is by conduction and radiation in roughly equal
  proportions;
- continual heating is needed in the decay phase of two-
  ribbon flares;
- continual heating is probably not needed in compact
  events;
- most of the soft-X-ray-emitting plasma results from
  "chromospheric evaporation".

Our goal was to reexamine these problems with the data from
SMM and other supporting instruments as well as to take
advantage of recent theoretical advances. SMM is capable
of measuring coronal temperatures more accurately and with
a better cadence than has been possible before. The SMM
data set is also unique in that the complete transit of an ac-
tive region was observed, with soft X-ray and UV images
being taken every few minutes. We are therefore able to es-
ablish the pre-flare conditions of the region and see whether
anything has changed as a result of the flare.

In the next subsection we describe the assumptions made
in attempting to determine the required plasma parameters.
The derived parameters for the five prime flares are pre-
sented, and the role of numerical simulations is discussed.
Finally, we consider the overall implications of our results
and discuss how both theory and observations have evolved
since the Skylab workshop.

5.3.2 The Basic Physical Expressions

The quantities needed for this study are defined in terms
of the fundamental plasma parameters of electron tempera-
ture (T_e), electron density (N_e), plasma volume (V), plasma
velocity (v), and height (h). The four basic energies that we
wish to obtain throughout the flares are the thermal energy
(E_{th}) of the plasma,

\[ E_{th} = 3 N_e k T_e V \text{ ergs} \]  

the kinetic energy (E_k) of the plasma,

\[ E_k = 1/2 M_p N_e V v^2 \text{ ergs} \]  

the potential energy (E_p) of the coronal plasma,

\[ E_p = M_p N_e V g_o h \text{ ergs} \]  

(\text{where } M_p \text{ is the proton mass and } g_o \text{ is the gravita-
tional acceleration at the solar surface}); and the stored ioniza-
